Note: Within nine months from the publication of the mention of the grant of the European patent, any person may give notice to the European Patent Office of opposition to the European patent granted. Notice of opposition shall be filed in a written reasoned statement. It shall not be deemed to have been filed until the opposition fee has been paid. (Art. 99(1) European Patent Convention).

## Description

[0001] The present invention relates to a method for manufacturing a sintered body of carbonitride alloy with titanium (Ti) as the main component and cobalt (Co) as the binder phase and which does not have any compositional gradients or center porosity concentration after sintering. This is achieved by processing the material in a specific manner to obtain a lower melting point of the liquid phase in the interior of the body compared to the surface while balancing the gas atmosphere outside the body with the alloy composition during all stages of the liquid phase sintering.

[0002] Titanium-based carbonitride alloys, so called cermets, are today well established as insert material in the metal cutting industry and are especially used for finishing. They comprise carbonitride hard constituents embedded in a metallic binder phase. The hard constituent grains generally have a complex structure with a core surrounded by a rim of a different composition. In addition to titanium, group VIa elements, normally both molybdenum and tungsten and sometimes chromium, are added to facilitate wetting between binder and hard constituents and to strengthen the binder by means of solution hardening. Group IVa and/or Va elements, i.e., zirconium, hafnium, vanadium, niobium and tantalum, are also added in all commercial alloys available today. All these additional elements are usually added as carbides, nitrides and/or carbonitrides. The grain size of the hard constituents is usually  $<2\text{ }\mu\text{m}$ . The binder phase is normally a solid solution of mainly both cobalt and nickel. The amount of binder phase is generally 3-25 wt%. Other elements are sometimes added as well, e.g. aluminium, which are said to harden the binder phase and/or improve the wetting between hard constituents and binder phase. Of course, commercially available raw material powders also contain inevitable impurities.

[0003] The most important impurity is oxygen, due to its high affinity to titanium. A normal impurity level for oxygen has historically been  $<0.3\text{ wt}\%$ . Recently, due to improved production methods for titanium-based raw materials, this level has been decreased to  $<0.2\text{ wt}\%$ , especially for grades with low nitrogen content. Very high oxygen levels are generally avoided since this may cause formation of carbon monoxide (CO) after pore closure during liquid phase sintering, which in turn leads to excessive porosity.

[0004] Common for all cermet inserts is that they are produced by the powder metallurgical methods of milling powders of the hard constituents and binder phase, pressing to form green bodies of desired shape and finally, liquid phase sintering the green bodies. Provided that good wetting is obtained between the liquid and the solid hard phase grains, strong capillary forces are obtained. The action of these forces is to shrink the porous body essentially isotropically, thereby eliminating porosity. The linear shrinkage is typically 15-30 %.

[0005] Sintering of titanium carbonitride-based cermets is a complex process, which requires precise control of all steps to obtain a sintered body with desired properties. Generally, after dewaxing, the material is heated under vacuum or in an inert atmosphere to 1250-1350 °C to enable desoxidation and denitrification of the material. Further heating to the final sintering temperature and subsequent cooling is normally done under vacuum or in an atmosphere that may contain both inert and reactive gases. Each of the steps influences the properties of the sintered material and must therefore be optimized carefully.

[0006] Conventional sintering processes yield sintered material with several drawbacks, such as lack of toughness and wear resistance. The sintered bodies commonly have a concentration of pores in the center and a surface with varying degrees of enrichment or depletion of the binder phase. Various attempts have been made to improve process control by varying the gas atmosphere during sintering.

[0007] Sintering in nitrogen ( $\text{N}_2$ ), accomplished in various ways, provides a means to limit denitrification, which is especially useful for cermets with high nitrogen content.

[0008] US 4,990,410 discloses a process for producing a cermet by liquid phase sintering in 0.1-20 torr  $\text{N}_2$  at temperatures  $\geq 1300\text{ }^\circ\text{C}$ . A nitrogen atmosphere is proven useful for modification of the near surface properties of sintered cermet bodies. US 5,059,491 discloses a process for producing a cermet with maximum hardness at a depth between 5 and 50  $\mu\text{m}$  from the surface by liquid phase sintering in  $\text{N}_2$  and cooling in vacuum. US 4,985,070 discloses a process for producing a high-strength cermet, which is accomplished by sintering the material in progressively increasing nitrogen pressure. US 5,145,505 discloses a process for producing a tough cermet with a binder-depleted surface by sintering in 5-30 torr  $\text{N}_2$ .

[0009] Sintering in CO has been found useful for obtaining improved control over the surface of sintered cermet bodies. WO 99/02746 discloses a process for producing sintered bodies without the common binder phase layer of 1-2  $\mu\text{m}$  thickness on the surface by sintering in CO at pressures of 1-80 mbar.

[0010] Sintering in CO- $\text{N}_2$  mixtures has been attempted to obtain improved properties of sintered bodies. US 5,856,032 discloses a process for producing Ti(C,N)-based cermets by liquid phase sintering in CO- $\text{N}_2$  mixtures. The gas mixture is used to modify the surface-near zone of the sintered body, down to a depth of 600  $\mu\text{m}$ . The desired composition of the gas mixture is dependent on the nitrogen content of the hard constituents whereas the total pressure needed is determined by the binder content. The sintered bodies are characterized in that the content of the Co and/or Ni-binder in a surface layer of 0.01-3  $\mu\text{m}$  depth in relation to the underlying core amounts to  $\leq 90\text{ }\%$  by mass in all cases.

**[0011]** US 6,017,488 discloses a process for producing sintered cermet bodies with Co binder. Sintering is performed in CO-N<sub>2</sub> mixtures, in which the partial pressures are kept below 20 mbar. The sintered bodies have a unique feature in that they have a macroscopic Co gradient, in which the Co content decreases essentially monotonously from the center of the body to its surface and reaches a Co content at a depth of 0-10 µm from the surface of 50-99 % of that in the center.

**[0012]** WO 98/51830 discloses a method of sintering titanium based carbonitride having a cobalt binder having a concentration gradient decreasing from the center of the product.

**[0013]** A series of titanium carbonitride-based alloys with Co binder are disclosed in EP-A-1 052 300, EP-A-1 054 073 and EP-A-1 069 196. These have superior performance in metal cutting applications, both with and without single or multiple layer wear-resistant coatings of carbides or nitrides of Ti and/or aluminum oxide. They show a unique behavior during sintering, being quite different from conventional cermets with Ni-Co binder. One feature is the high content of Ta, i.e. ≥2 at%, preferably 4-7 at%, which increases the nitrogen activity in the material during sintering. Another feature is the optimization of the raw materials that has led to significant improvement of performance in metal cutting. Due to these two features these materials differ substantially from the conventional and hence they require a sintering process, unlike the ones that are commonly used. If they are sintered according to the processes disclosed in US 6,017,488 or US 5,856,032, they will melt in the conventional way, i.e. from the surface inwards, leading to gas entrapment and unacceptable porosity, which must be avoided in order to fully utilize the potential of these materials.

**[0014]** It is an object of the present invention to provide a method of manufacturing said class of titanium carbonitride-based alloys having Co as a binder and high Ta content. The object is achieved by the method according to the claim.

**[0015]** Fig. 1 is an EMPA (Electron Micro Probe Analysis) line scan across an insert of a Ti(C,N)-(Ti,Ta,W) (C,N)-Co alloy sintered in the presently invented process.

**[0016]** Fig. 2 is an EMPA line scan across an insert of a Ti(C,N)-(Ti,Ta,W)(C,N)-Co alloy sintered in a reference process.

**[0017]** Fig. 3 is an EMPA line scan across an insert of a Ti(C,N)-(Ti,Ta,W)(C,N)-Co alloy sintered in a reference process.

**[0018]** Fig. 4 is an EMPA line scan across an insert of a Ti(C,N)-(Ti,W)(C,N)-Co alloy sintered in a reference process.

**[0019]** It has quite surprisingly turned out, for the alloy class specified above, that by utilizing the invented process a sintered body without a macroscopic Co gradient can be obtained while maintaining the favorable melting, i.e. nucleation in the center propagating towards the surface. This favorable outcome is achieved by dewaxing the green bodies, followed by increasing the temperature under vacuum to 1250-1350 °C to allow desoxidation and controlled denitrification of the hard phase grains. The denitrification is controlled by the temperature increment and temperature plateaus at suitable levels. Subsequently, sintering is carried out in a predefined gas atmosphere. Different gas compositions are required for

- (1) the temperature rise up to the final sintering temperature,
- (2) the plateau at the final temperature and
- (3) the temperature decrease to ≤1200 °C.

**[0020]** (1) The partial pressures of CO and N<sub>2</sub> should be kept constant or increased stepwise or monotonously while increasing the temperature up to the final sintering temperature to balance the increasing gas generation rate in the green bodies. Too low pressures will result in macroscopic Co gradients, whereas too high pressures will revert the melting process, leading to center porosity concentration. The levels for CO and N<sub>2</sub> for the onset of sintering are 0.25-3 mbar, preferably 0.5-1.5 mbar. The partial pressure levels for CO and N<sub>2</sub> when reaching the final sintering temperature are 1-10 mbar, preferably 2-6 mbar and 0.5-3 mbar, preferably 1-2 mbar, respectively.

**[0021]** (2) Controlling the gas atmosphere during the increment from 1250-1350 °C up to the final sintering temperature is useful for eliminating the macroscopic Co gradient. However, the materials for which the currently invented process is useful suffer from enrichment of hard constituent containing W and Ta in a surface zone of ≤500 µm depth, accompanied by depletion of Co. The enrichment is such that in some cases the contents of W and Ta in a range 0-10 µm from the surface are ≥20 % higher than that in the center of the body. It has surprisingly been found out that this enrichment can be eliminated by controlling the composition of the gas atmosphere during the plateau at the final sintering temperature. Both CO and N<sub>2</sub> must be controlled to achieve elimination of compositional gradients at a depth of ≤500 µm from the surface of the body. The CO and N<sub>2</sub> partial pressures are 0.5-5 mbar, preferably 1-3 and 0.25-3 mbar, preferably 0.5-2 mbar, respectively during the plateau at the final sintering temperature.

**[0022]** (3) Controlling the gas atmosphere during temperature increment and the plateau at the final sintering temperature is not enough to obtain acceptable properties of the actual surface of the sintered body. It has been found out that by choosing proper CO and N<sub>2</sub> pressures when decreasing the temperature to a level well below the liquidus temperature of the binder phase, the surface composition at a depth of 0-10 µm is essentially the same as in the bulk. Surface layers of binder or hard constituents can thus be circumvented. The partial pressures of CO and N<sub>2</sub> are 0.25-3

mbar, preferably 0.5-2 mbar and 0.25-3 mbar, preferably 0.5-2 mbar, respectively during cooling from the final sintering temperature to  $\leq 1200$  °C.

#### Example 1

[0023] TNMG 160408-PF inserts were pressed using a powder mixture of nominal composition (at%) Ti 37.1, W 3.6, Ta 4.5, C 30.7, N 14.5 and Co 9.6. The green bodies were dewaxed in H<sub>2</sub> at a temperature below 350 °C. The furnace was then evacuated and pumping was maintained throughout the temperature range 350-1300 °C. From 350 to 1050 °C, a temperature ramp of 10 °C/min was used. From 1050 to 1300 °C/min, a temperature ramp of 2 °C/min was used. The temperature was held at 1300 °C in vacuum for 30 min. Subsequently, the vacuum valve was closed and the temperature was increased to 1480 °C, using a ramp of 2 °C/min. Up to 1310 °C, the furnace pressure was allowed to increase due to outgassing of the porous bodies. During subsequent heating to the final sintering temperature, followed by cooling to 1200 °C, gas mixtures were allowed to flow through the furnace while maintaining a constant pressure of 8 mbar. From 1310 to 1480 °C the gas mixture contained 8.3 vol% CO, 8.3 vol% N<sub>2</sub>, the balance being argon (Ar). During liquid phase sintering for 90 min at 1480 °C the gas mixture contained 29.2 vol% CO, 12.5 vol% N<sub>2</sub>, the balance being Ar. From 1480 to 1200 °C a cooling rate of 3.5 °C/min was applied, while using a gas mixture of composition 16.7 vol% CO, 12.5 vol% N<sub>2</sub>, the balance being Ar.

[0024] Polished cross sections of the inserts were prepared by standard metallographic techniques and characterized using optical microscopy and electron microprobe analysis (EMPA). Optical microscopy showed that the inserts had an evenly distributed residual porosity in porosity class A04 or better throughout the sintered bodies. The pores were evenly distributed, without any pore concentration in the center of the body. Figure 1 shows an EMPA line scan analysis of Co, W, N and C ranging from one side of the insert, through the interior of the material to the opposite surface. Clearly the concentrations of all elements are constant throughout the insert, within reasonable measurement limits and statistical fluctuations.

#### Example 2 (comparative)

[0025] In a second experiment, inserts of nominal composition (at%) Ti 35.9, W 3.6, Ta 4.3, C 27.2, N 16.6 and Co 12.4 were manufactured in an identical manner as described in Example 1, except that the gas, that was allowed to flow through the furnace was Ar during the temperature increment from 1310 to 1480 °C. In this case a typical macroscopic Co gradient was observed, having a parabolic shape, as can be seen in Figure 2, showing an EMPA line scan analysis. The Co content at a depth of 0-10  $\mu\text{m}$  from the surface is 15 % lower than that in the center of the insert. Optical microscopy showed that the inserts had an evenly distributed residual porosity in porosity class A04 or better throughout the sintered bodies.

#### Example 3 (comparative)

[0026] In a third experiment, inserts of nominal composition (at%) Ti 37.1, W 3.6, Ta 4.5, C 30.7, N 14.5 and Co 9.6 were manufactured in an identical manner as described in Example 1, except that the gas mixture that was allowed to flow through the furnace was of composition CO 50 vol% and N<sub>2</sub> 50 vol% at a furnace pressure of 20 mbar during the temperature increment from 1310 to 1480 °C. Optical microscopy of a cross section of an insert showed a concentration of pores in the center of the insert, porosity class worse than A08, whereas porosity was in porosity class A04 in a zone  $\leq 500$   $\mu\text{m}$  from the surface. EMPA line scan analysis indicated a minimum in Co content in the center of the insert. These two observations lead to the conclusion that the binder phase has melted from the outside and inward, trapping gas generated during temperature increment, resulting in unacceptable porosity and unwanted compositional gradients.

#### Example 4 (comparative)

[0027] In a fourth experiment, inserts of nominal composition (at%) Ti 37.1, W 3.6, Ta 4.52, C 30.7, N 14.5 and Co 9.6 were manufactured in an identical manner as described in Example 1, except that the gas mixture that was allowed to flow through the furnace was of varying composition during the temperature increment from 1310 to 1480 °C at varying furnace pressures. Moreover, the gas composition was different during liquid phase sintering and cooling to  $\leq 1200$  °C.

[0028] The table below, summarizes the gas composition in the furnace during sintering.

Temperature	Gas composition (vol%)			Furnace pressure
(°C)	CO	N <sub>2</sub>	Ar	(mbar)
1310-1340	50	50	0	1.5
1340-1370	55	45	0	3
1370-1400	67	33	0	4
1400-1430	75	25	0	5.5
1430-1480	75	25	0	6.5
1480 (plateau)	37	7	56	6
1480-1200	23	7	70	6

[0029] For comparison, inserts of another nominal composition (at%) Ti 40.2, W 3.6, C 27.2, N 16.6 and Co 12.4, i.e. without Ta, were manufactured in an identical manner.

[0030] Figure 3 and 4 show EMPA line scan analyses of the inserts made of the new alloy with Ta and the reference alloy without Ta, respectively. It is concluded from Figure 3 that no macroscopic Co gradient is observed of the type, shown in Figure 2. Hence, the gas atmosphere during the temperature increment from 1310 to 1480 °C is well balanced. However, there is a clear depletion of Co in a zone  $\leq 500 \mu\text{m}$  from both surfaces. The Co content at a depth of 0-10  $\mu\text{m}$  from the surface is 12 % lower than that in the center of the insert. This indicates an unbalance in the gas atmosphere during the plateau at the sintering temperature. The reference material shows essentially no compositional gradients. Optical microscopy showed residual porosity in porosity class A04 or better, throughout the insert for the Ta-containing material and no residual porosity, porosity class A00, for the reference material, without Ta.

## Claims

1. Method of manufacturing by liquid phase sintering a body of titanium-based carbonitride alloy, containing hard constituents based on Ti, W and Ta in a Co binder phase, characterized in that the atomic N/(C+N) ratio is 25-50 at%, the Ta content is at least 2 at%, preferably 4-7 at%, the W content is at least 2 at%, preferably 3-8 at% and the Co content is 5-25 at% and that sintering is performed under such conditions that the liquid binder phase forms in the center of the body first and the melting front then propagates outwards towards the surface without generating a macroscopic binder phase gradient by

- during temperature rise from a temperature 1250-1350 °C to the final sintering temperature, being 1370-1550 °C, the temperature increment rate is 0.5-5 °C/min
- during cooling between the sintering temperature and  $\leq 1200^\circ\text{C}$  the temperature decline rate is 0.5-5 °C/min
- during temperature rise from a temperature 1250-1350 °C to the final sintering temperature N<sub>2</sub> and CO partial pressures are kept constant or that N<sub>2</sub> and CO partial pressures are increased monotonously or stepwise and the N<sub>2</sub> and CO partial pressures are 0.25-3 mbar, preferably 0.5-1.5 mbar at 1300 °C and that the N<sub>2</sub> and CO partial pressures are 0.5-3 mbar, preferably 1-2 mbar and 1-10, more preferably 2-6 mbar respectively when reaching the final sintering temperature
- the N<sub>2</sub> and CO partial pressures are 0.25-3 mbar, preferably 0.5-2 mbar and 0.5-5 mbar, preferably 1-3 mbar respectively during the hold at the final sintering temperature
- the N<sub>2</sub> and CO partial pressures are 0.25-3 mbar, preferably 0.5-2 mbar and 0.25-3 mbar, preferably 0.5-2 mbar respectively during cooling from the final sintering temperature to  $\leq 1200^\circ\text{C}$  and the holding time at final sintering temperature is 30-120 minutes.

## Patentansprüche

1. Verfahren zur Herstellung eines Körpers von Carbonitridlegierung auf Titanbasis, die harte Bestandteile auf der Basis von Ti, W und Ta in einer Co-Bindephase umfaßt, dadurch gekennzeichnet, daß das Atomverhältnis N/(C+N) 25-50 at% beträgt, daß der Ta-Gehalt wenigstens 2 at%, vorzugsweise 4-7 at% beträgt, der W-Gehalt wenigstens 2 at%, vorzugsweise 3-8 at% ist und der Co-Gehalt 5-25 at% beträgt und daß das Sintern unter solchen Bedingungen erfolgt, daß die flüssige Bindephase sich zunächst in der Mitte des Körpers bildet und die Schmelzfront dann nach außen zu der Oberfläche hin ohne Erzeugung eines makroskopischen Bindephasengradienten voranschreitet, indem

- während des Temperaturanstiegs von einer Temperatur von 1250-1350°C zu der endgültigen Sinteremperatur von 1370-1550°C ansteigt, wobei die Geschwindigkeit des Temperaturanteils 0,5-5°C/min. beträgt,
- während des Kühlens zwischen der Sinteremperatur und  $\leq 1200^\circ\text{C}$  die Temperatur eine abfallende Geschwindigkeit von 0,5-5°C/min. hat,
- während des Temperaturanstiegs von einer Temperatur von 1250-1350°C auf die Endsinterungstemperatur bei den  $\text{N}_2$ - und CO-Partialdrücken konstant gehalten werden oder die stufenweise
- die  $\text{N}_2$ - und CO-Partialdrücke 0,25-3 mbar, vorzugsweise 0,5-1,5 mbar bei 1300°C sind und daß die  $\text{N}_2$ - und CO-Partialdrücke 0,5-3 mbar, vorzugsweise 1-2 mbar bzw. 1-10 mbar, stärker bevorzugt 2-6 mbar betragen, wenn sie die Endsinteremperatur erreichen,
- die  $\text{N}_2$ - und CO-Partialdrücke 0,25-3 mbar, vorzugsweise 0,5-2 mbar sowie 0,5-5 mbar, vorzugsweise 1-2 mbar während des Haltens auf der Sinterendtemperatur sind,
- die  $\text{N}_2$ - und CO-Partialdrücke 0,25-3 mbar, vorzugsweise 0,5-2 mbar, bzw. 0,25-3 mbar, vorzugsweise 0,5-2 mbar während des Kühlens von der Endsinteremperatur auf  $\leq 1200^\circ\text{C}$  sind und die Verweilzeit bei der Endsinterungstemperatur 30-120 Minuten beträgt.

## Revendications

1. Procédé pour fabriquer, au moyen d'un frittage avec phase liquide, un corps d'alliage de carbonitride à base de titane, contenant des éléments constitutifs durs à base de Ti, W et Ta dans une phase liante de Co, caractérisé en ce que le rapport atomique  $\text{N}/(\text{C}+\text{N})$  va de 25% à 50% atomique, la teneur en Ta est d'au moins 2% atomique, de préférence de 4% à 7% atomique, la teneur en W est d'au moins 2% atomique, de préférence de 3% à 8% atomique et la teneur en Co va de 5% à 25% atomique, et en ce que le frittage est réalisé dans des conditions telles que la phase liante liquide se forme d'abord dans le centre du corps et que le front de fusion se propage ensuite vers l'extérieur vers la surface sans produire de gradient de phase liante macroscopique, dans lequel
  - pendant l'élévation de la température d'une température de 1250°C à 1350°C à la température finale de frittage, allant de 1370°C à 1550°C, la vitesse d'élévation échelonnée de la température va de 0,5°C à 5°C/min,
  - pendant le refroidissement entre la température de frittage et une température de 1200°C ou moins, la vitesse d'abaissement de la température va de 0,5°C à 5°C/min,
  - pendant l'élévation de la température d'une température de 1250°C à 1350°C à la température finale de frittage, les pressions partielles de  $\text{N}_2$  et de CO sont maintenues à un niveau constant ou les pressions partielles de  $\text{N}_2$  et de CO croissent de façon monotone ou graduelle et
  - les pressions partielles de  $\text{N}_2$  et de CO vont de 0,25 mbar à 3 mbars, de préférence de 0,5 mbar à 1,5 mbar à une température de 1300°C et les pressions partielles de  $\text{N}_2$  et de CO vont de 0,5 mbar à 3 mbars, de préférence respectivement de 1 mbar à 2 mbars et de 1 mbar à 10 mbars, de manière plus particulièrement préférée de 2 mbars à 6 mbars, au moment où la température finale de frittage est atteinte,
  - les pressions partielles de  $\text{N}_2$  et de CO vont de 0,25 mbar à 3 mbars, de préférence respectivement de 0,5 mbar à 2 mbars et de 0,5 mbar à 5 mbars, de manière plus particulièrement préférée de 1 mbar à 3 mbars, pendant le maintien à la température finale de frittage,
  - les pressions partielles de  $\text{N}_2$  et de CO vont de 0,25 mbar à 3 mbars, de préférence respectivement de 0,5 mbar à 2 mbars et de 0,25 mbar à 3 mbars, pendant le refroidissement à partir de la température finale de frittage à une température de 1200°C ou moins, et la durée de maintien à la température finale de frittage va de 30 minutes à 200 minutes.
